## Abstract

The two commonly-used performance data types in the super-computing community, statistics and event traces, are discussed and compared. Statistical data are much more compact but lack the probative power event traces offer. Event traces, on the other hand, are unbounded and can easily fill up the entire file system during program execution. In this paper, we propose an innovative methodology for performance data gathering and representation that offers a middle ground. Two basic ideas are employed: the use of averages to replace recording data for each instance and “formulae” to represent sequences associated with communication and control flow. The user can trade off tracing overhead, trace data size with data quality incrementally. In other words, the user will be able to limit the amount of trace data collected and, at the same time, carry out some of the analysis event traces offer using space-time views. With the help of a few simple examples, we illustrate the use of these techniques in performance tuning and compare the quality of the traces we collected with event traces. We found that the trace files thus obtained are, indeed, small, bounded and predictable before program execution, and that the quality of the space-time views generated from these statistical data are excellent. Furthermore, experimental results showed that the formulae proposed were able to capture all the sequences associated with 11 of the 15 applications tested. The performance of the formulae can be incrementally improved by allocating more memory at run-time to learn longer sequences.

## 1. Introduction

Computing today increasingly depends on the effective utilization of multiprocessors. Systems currently available range from those with tightly-coupled processors to those with a network of workstations. Innovation in hardware technologies continuously reduce the communication time between processing nodes as well as access latencies across the memory hierarchy to support computing in this new environment. Unfortunately, the software infrastructure (*e.g.* programming languages, compilers, operating systems, and performance monitoring and prediction tools)

available today still has not kept pace with the state-of-the-art multiprocessing hardware [Pan91, SMS95]. In particular, the lack of useful, accurate facilities for measuring and analyzing program performance is particularly distressing, since performance is the *raison d'être* for parallelism.

### **1.1 Performance Analysis Systems**

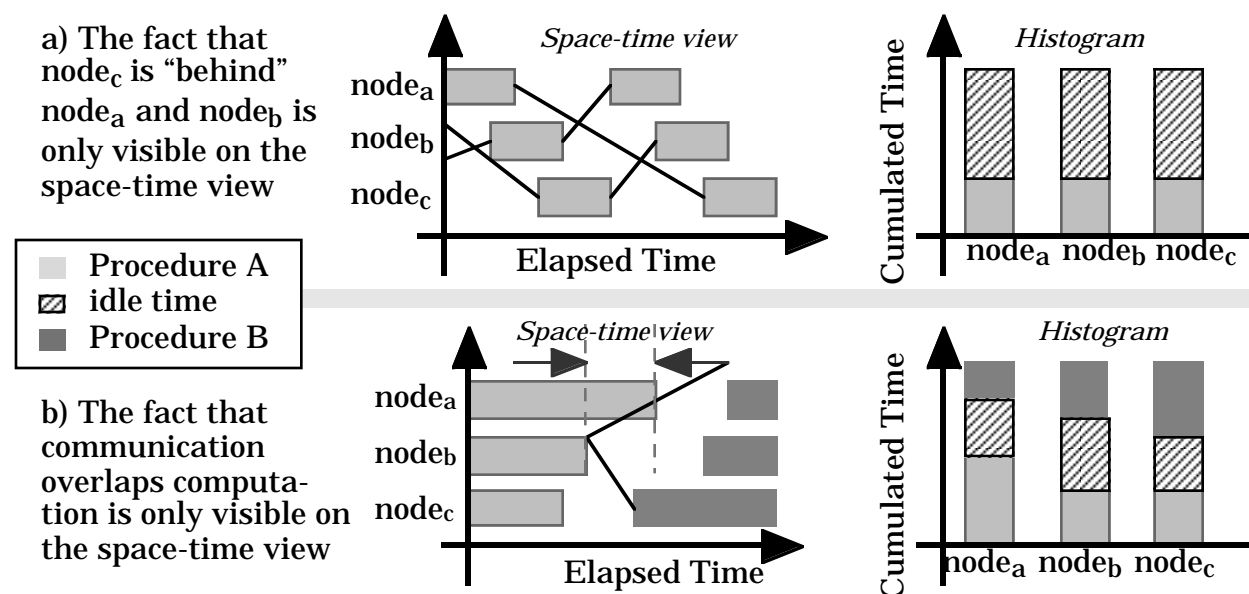

Traditional performance-analysis systems (*e.g.* *gprof*) that generate textual information have proven quite effective for sequential programs. Metrics based on the distribution of elapsed time across the program can systematically direct the user towards time consuming regions of code where performance should be improved. Unfortunately, such simple measures are insufficient for parallel programs and may even be misleading [HIM91]. This problem arises primarily because aggregate values do not necessarily capture the dynamic interactions between various processes (and processing nodes) involved in the computation. In order to fully understand the performance of a particular program on a particular machine, a performance tool must capture and analyze dynamic execution characteristics.

Visualization has been used extensively to represent simulation results for many complex physical systems. In the past five years, the application of visualization technologies to manage the vast amount of performance data collected in multiprocessors has also been proposed. Many tools supporting performance visualization are available today, either in the public domain (*e.g.* *AIMS* [YSM95], *Pablo* [RO\*91], *Paradyn* [MC\*95], and *ParaGraph* [HE91]) or as part of a multiprocessor's system software (*e.g.* *CXTRACE* on Convex's SPP-1, *ParAid* on Intel's Paragon, *MPP Apprentice* on CRI's T3D, *PRISM* on TMC's CM5, and *PV* on IBM's SP2). Typically, performance data are displayed *post-mortem*. These displays provide valuable feed-back about users' choice of parallel algorithm, strategies for load balancing and data distribution, as well as how the application will scale with increasing numbers of processing nodes and problem sizes. A good survey of some state-of-the-art research efforts can be found in [PMY95, SK90].

### **1.2 Statistics vs. Event Traces: A Comparison**

Broadly speaking, there are two kinds of performance data: *statistics* and *event traces*. *Statistics* are concerned with counts and duration: *e.g.* how many times a procedure has been called and, on average, how long it took to complete. *Event traces*, on the other hand, record the exact sequence (and in most cases, the actual time) of actions that took place during program execution. Furthermore, when the clocks across processing nodes are synchronized, event traces can help provide a global picture of what took place (*e.g.* how long a message took to reach node *b* from node *a*). As of today, all the trace tools that animate parallel program execution (*e.g.* using space-time diagrams) require synchronized event traces from multiple nodes.

One might suggest that event traces should always be gathered since they contain much more information. Unfortunately, event traces in general are large and the size of the trace file is not predictable before program execution. Furthermore, the collection process itself is expensive and requires a lot of resources. The most intrusive activity to support event traces involves the need to allocate memory buffers dynamically in order to save the performance data and flushing to disk when these buffers are full. In fact, two commercial vendors (CRI's *MPP-Apprentice* and TMC's *PRISM*) have opted not to support event traces, possibly to avoid excessive perturbation on observed program behavior. In both cases, the user locates bottlenecks by studying the amount of time a procedure or source line consumes and the activity that took place during this time. The reasons so many other vendors (e.g. *CXTRACE* on Convex's SPP-1, *ParAid* on Intel's Paragon, and *PV* on IBM's SP2) are still supporting event tracing can probably be explained by the differences of the two representations as discussed below.

**Figure 1. Comparing space-time views vs. histograms in their abilities to capture program behavior in 2 cases: a) computation/communication overlap, and b) load-imbalance.**

Figure 1 compares the abilities of two visual representations supporting parallel program behavior analysis, histograms vs. space-time views. Two interesting parallel program behavior patterns involve *synchronized behavior across nodes* and *communication-computation overlap*. In the space-time views shown on the left of Figure 1, each horizontal bar indicates activity that took place at a node during a given time interval. "White spaces" indicate idleness, possibly waiting for the arrival of a message. Messages are indicated as lines drawn from the sender node to the receiver node. Each column of the histograms on the right plots accumulated time for various ac-

tivities for the corresponding node. Basically, node<sub>a</sub>, node<sub>b</sub>, and node<sub>c</sub> were all executing *Procedure A* at the beginning of the time interval being monitored. In Figure 1a, nodes exchanged messages in a cyclic pattern. The fact that node<sub>c</sub> was “behind” node<sub>a</sub> and node<sub>b</sub> is only visible on the space-time view. In Figure 1b however, after *Procedure A* terminated, node<sub>b</sub> sent messages to node<sub>a</sub> and node<sub>c</sub> before they all entered *Procedure B*. Although the user may suspect the existence of load imbalance based on the histogram, the fact that communication overlaps computation is only visible on the space-time view.

Table 1 gives a more detailed comparison between statistics and event traces in three areas: collection requirements, trace file size and analyses these traces support. Two observations need to be highlighted:

1. Event traces are relatively larger and unbounded. This can be a severe problem in practice.
2. Event traces support a much richer variety of analyses critical towards understanding the behavior of parallel programs.

It is, therefore, not surprising that a lot of tools available today are still based on event traces.

### **1.3 Trace File Reduction Attempts**

As mentioned above, event traces contain much richer information, but unfortunately the size of a trace file is unbounded. Attempts have been made to reduce trace file size. In the Automated Instrumentation and Monitoring System (*AIMS*) [YSM95] that was developed at NASA Ames Research Center, two techniques for trace file reduction had been considered:

1. Merging trace records that always occur in pairs:
  - a) Message (*e.g.* send, receive, broadcast) blocking and unblocking.
  - b) Code-block (*e.g.* procedure, loop) entry and exit.
2. Using binary encoding for trace records.

In the first technique, a new trace record type was defined and used in place of two individual records to eliminate some duplicate fields (*e.g.* the message type, size, and, tag). Our studies indicated that trace record merging resulted in a reduction of 27% of the number of trace records, which translated to an average reduction of 38% in actual trace file length in ASCII. Binary trace encoding is the second technique to reduce trace file size. Researchers working on Pablo [RO\*91] reported 40% savings with the use of binary (vs. ASCII) representation. Our own calculations also indicated similar savings (from 40% to 50%).

In summary, the trace file would only shrink by a factor of 4 even if both techniques were applied simultaneously. This was insufficient because applications of interests will scale up an order of magnitude in problem size as well as number of nodes. Furthermore, no matter how compact the representation may become, the generation of event traces leaves the trace file length

unbound. A fundamental re-thinking of the process of performance instrumentation, monitoring and trace representation is required in order to limit trace file length while preserving the rich content available in event traces.

		Statistics	Event Traces
<b>Trace collection overhead</b>	reading system clock	√	√
	synchronizing clocks across nodes		√
	allocate memory buffer	√	√
	flushing to disk during execution		√
	processing requirements	simple integer arithmetic	memory management required
<b>Trace file size</b>		predictable	unbounded
<b>Trace Analysis Supported</b>	classification of % time spent on various activities	√	√
	code block (such as procedures, loops, and user-defined blocks) duration	average values	distinguishes each instance of invocation
	alignment of code blocks, parallelism profiles, critical paths		√
	load imbalance due to the fact that identical code blocks take different times to execute across nodes	may suggest possibility	obvious and conclusive identification
	load imbalance due to the fact that receiver is blocked before sender is ready, messages received out of order, identify communication/computation overlap, message transmission time		√

**Table 1. Statistics vs. event traces — comparison of trace file contents**

## **1.4 Outline of Paper**

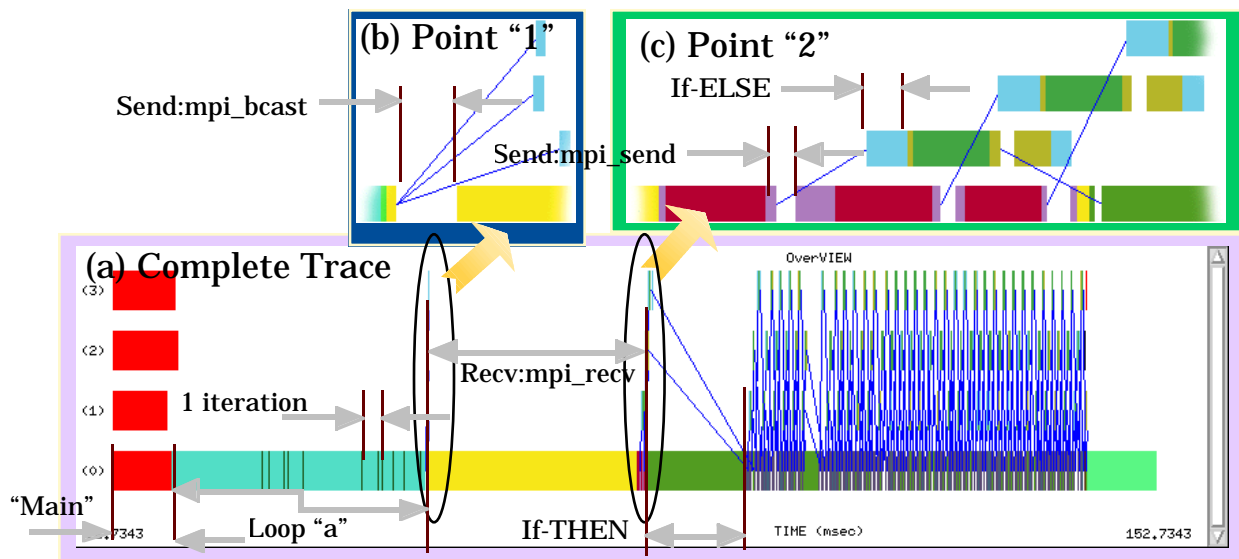

This paper proposes an innovative approach for instrumentation, monitoring and trace representation to support a rich variety of performance analyses and, at the same time, putting stringent constraint on trace file size. Sections 2 and 3 describe how a *space-time view* can be constructed based on a fixed sized trace file. Sections 4 and 5 report preliminary experimental results, inviting the reader to consider whether these constructed *space-time views* do indeed reflect performance problems correctly and support the kind of analyses mentioned in Table 1.

## 2. Constructing Space-Time Views based on Statistics

### 2.1 Understanding the Components of a Space-Time View

Figure 2 shows a space-time view obtained from a detailed trace of a parallel matrix multiplication program (or, `matmul`). The program was written in FORTRAN, using the MPI message passing library, and executed on four nodes of an IBM/SP2. Figure 2(a) shows the complete execution history. There are three basic features: color bars, “white spaces” and lines:

1. Each color bar indicates the start and end times for a particular code segment.
2. Each segment of “white space” indicates the start and end times of idling/blocking.
3. Each line segment indicates the origin, destination, and, send/receive times of a message.

**Figure 2. Analysis of the space-time diagram (a) complete execution trace of `matmul`; (b) zoomed-in view at point 1; (c) zoomed-in view at point 2**

When Figure 2 is further analyzed with reference to the source code, a few more observations can be made:

- `Matmul` is an *spmd* (single program multiple data) parallel application, all nodes share the same initialization sequence (labeled “*Main*” in Figure 2).
- Node 0 behaves differently from the rest of the nodes because the code contains conditionals of the form “`if (node_id == 0) then ... ; else ...`”. Two features that distinguished the behavior of Node 0 from the rest of the nodes are clearly distinguishable:
  - a) After initialization, *node 0* executed *Loop “a”* a few times while the rest waited.
  - b) The “*then*” part of one conditional was executed at *node 0* (Figure 2(a)) whereas the “*else*” portions of some other conditionals were executed at the rest of the nodes (Figure 2(c)).

- The duration of each iteration in a loop (e.g., *Loop “a”*) differs.
- Different nodes idle for different times awaiting the arrival of messages (e.g. as shown in Figure 2(a)). Idling could be caused by message sending (e.g. a broadcast as shown in Figure 2(b) or a point-to-point send as shown in Figure 2(c)).

## 2.2 Refining Our Requirements

Based on these observations, the requirements for constructing space-time views can be stated in terms of requirements to construct its three major components: the color bars, white spaces and message lines as summarized in Table 2. For example, requirement-1 in Table 2 implies that the control flow (for example, the branch sequence of a conditional) has to be monitored and reproduced in the right order. The requirements for making trace file length fixed and predictable before program execution can be formalized as shown in Table 3. It is not difficult to see how these two sets of requirements cannot be met simultaneously. A simple example involves a program in which process 0 sends messages to randomly picked processes for a random number of times. The list of message receivers is unboundedly long and arbitrary. The data required for constructing a space-time view can only be captured by an unbounded event list. Fortunately, most real programs do not behave in a completely random fashion. This leaves room for the possibility of

1. *Drawing color bars:*
  - a) identify the boundaries of all sequential code blocks of the program (these include, *procedures* and *loops*, *if-then-else*'s, and targets for *goto*'s etc.),
  - b) record the duration of each code block, and
  - c) reconstruct the sequence in which these code blocks occur.
2. *Drawing white spaces:*
  - a) identify all *blocking* constructs (e.g. sends, receives, broadcasts, barriers, waits etc.),
  - b) record the duration of each idling instance, and
  - c) record the sequence in which these white spaces occur with respect to the color bars.
3. *Drawing message lines:*
  - a) record the receiver for each *send construct* and the sender for each *receive construct*,
  - b) record the *ID* or *type* for each message so that send's and receive's can be matched correctly<sup>1</sup>, and
  - c) reconstruct the sequence in which these send's and receive's occur.

**Table 2. Requirements for performance data content to construct a space-time view**

1. The length of the trace file should be independent of the input data (e.g. no. of iterations, problem size).
2. Trace file size may scale with the number of nodes on which the execution takes place. We feel that the number of storage devices could easily scale nicely with the number of nodes.
3. Trace file size may vary with different programs but should be independent of input data.
4. Performance data needs to be gathered for the entire program, not limited to a portion of the execution at the beginning.

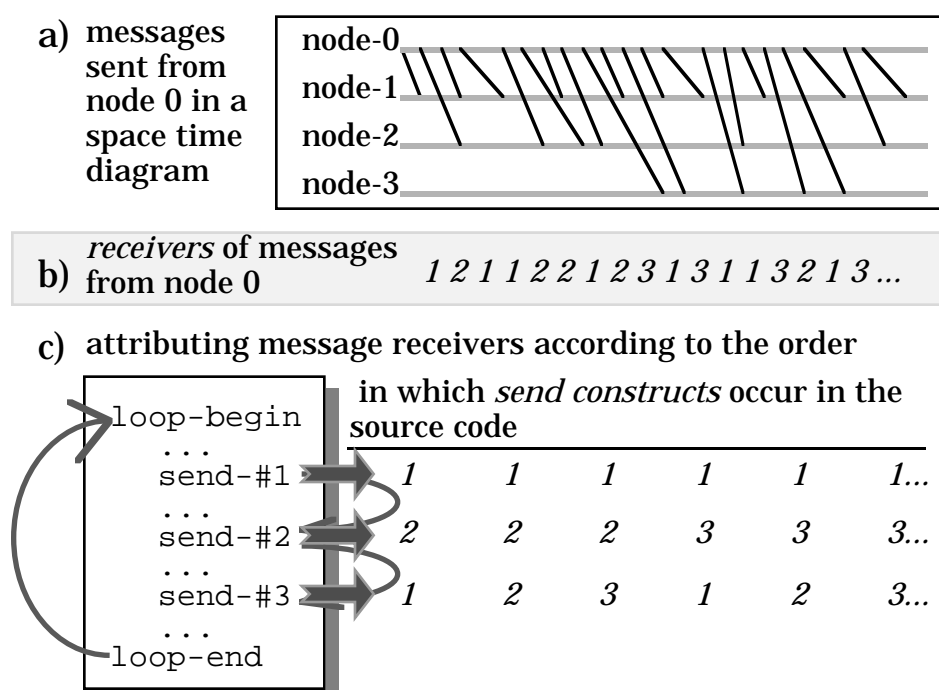

**Table 3. Defining “fixed” trace file length**

<sup>1</sup> For example, if node 1 sends two messages to node 2 in rapid succession; having the message ID or type will help determine whether the messages are received out of order.

using patterns to capture program behavior.

## 2.3 Collecting Data for a Space-Time View

Two basic ideas are employed to help limit the length of the trace file before program execution: the use of “averages” to replace recording data for each instance, and “formulae” to represent infinitely long sequences of values. The first idea is relatively straightforward: statistical information about total time spent in each code block and the number of times each code block<sup>2</sup> executes is gathered. The space-time view constructed based on this data will only reflect “average duration” for each code block (*e.g.* the total time for executing a loop can be correctly represented while it will not be possible to pinpoint exactly how long a particular iteration actually took).

**Figure 3. Analyzing message patterns generated by a parallel program**

The second idea is best illustrated by considering message lines on the space-time view (*e.g.*, as shown in Figure 3a): in order for a line to be drawn, a unique sender and a unique receiver must be associated with each message. For all the send’s along each time line to be correctly connected to other time lines, the sequence of message receivers must be correctly reproduced (*e.g.*, as shown in Figure 3b). Now this seemingly complex sequence of receiver nodes originates from a sequence of send constructs (*e.g.*, as shown in Figure 3c (left)) that was executed. When the sequence of receivers are broken down according to the actual source code constructs (as shown in Figure 3c

<sup>2</sup> A code block would include loops, procedures, sends/receives, as well as any “basic block” defined in the classical sequential sense.

(right)), simpler patterns usually emerge<sup>3</sup>. This concept of associating sequences with individual source code construct can actually be applied to six categories of constructs:

- i. the sequence of receivers for each sending construct,
- ii. the sequence of senders for each receiving construct,
- iii. the sequence of message tags for each send construct,
- iv. the sequence of message tags for each receive construct,
- v. the way in which branches are taken at conditional statements, and
- vi. the number of times a loop executes when the loop is encountered.

A methodology for *learning* the behavior of each construct as well as a suitable representation for these patterns has to be chosen. Although there is no guarantee that any of these sequences can be captured by a finite “formulae” (*c.f.* behavior that are designed to be random), it remains the subject of further experimentation as to what percentage of program constructs are, in fact, amenable to this kind of analysis.

Four basic categories of formulae are proposed for learning and reproducing sequences associated with program constructs (see Table 4):

1. IDENTITY — repetition of one value.
2. GENERAL — non-repeating values.
3. ITERATION — iterative series with constant difference between individual terms.
4. CYCLE — after some sort of prologue, the rest of the series can be represented as a repetition of a fixed number of values.

Formula Type	Formula	Example
(id) identity	$a^n$	a a a a a a a a a a
(ge) general	$a^r b^s c^t d^u e^v$	a a a a b c c d d d d e
(it) iteration	$(a (a+i) (a+2i) \dots (a+ki))^n$	1 3 5 7 9 1 3 5 7 9
(cy) cycle	$a^p c^q (a^r b^s c^t d^u e^v)^n$	d a d b b b c c d d d d b

**Table 4. Four simple formulae used in this experiment**

At run-time, the performance monitor determines whether a sequence can be captured with a formula, and if so, which one. The user allocates a fixed amount of memory for this purpose be-

---

<sup>3</sup> Program segments resemble components of a complex machinery built for a specific purpose. Although the behavior of the entire machine may appear complex, its components tend to exhibit relatively simple and predictable behavior patterns.

fore program execution. Of course, longer repeating sequences could be learned if more memory were available. Nevertheless, it should also be noted that are many possible formula types and some series cannot be captured by a fixed-length formula.

### 3. The *AIMS* Implementation

#### 3.1 Basics of *AIMS*

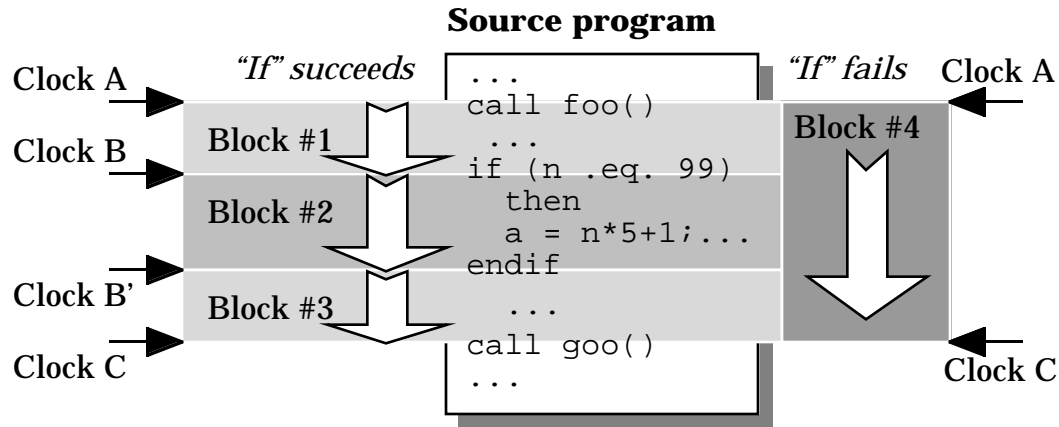

The *Automated Instrumentation and Monitoring System*, or *AIMS* [YSM95], has been developed at NASA Ames Research Center, under the High Performance Computing and Communications Program. *AIMS* consists of a suite of software tools for measurement and analysis of parallel program performance. An instrumentor first parses the application's source code to insert instrumentation at selected points. Upon execution of the instrumented program (linked with a machine-specific monitor library), a stream of events is collected into a trace file. Runtime monitoring perturbs program execution and can significantly alter the recorded communication characteristics and computation times. Such intrusion is removed by an intrusion-compensation module, using appropriate communication-cost models for the underlying architecture [YL93]. The compensated trace file thus yielded can then be input to various post-processing tools that analyze the performance characteristics of a program.

*AIMS* provides two post-processing tools for performance visualization: the *View Kernel (VK)* to display the dynamics of program execution using a space-time view, and the *Performance Index and Statistics Kernel (Xisk)* to view statistical performance data and highlight the most time consuming procedures and data structure interactions that may need to be tuned.

In the next few sections we proceed to discuss how *AIMS* is actually modified to collect statistical data, learn and record formulae for sequences, and reconstruct a space-time view for performance analysis.

#### 3.2 Instrumentation

Instrumentation is essentially a process of source-to-source program transformation. *AIMS*'s instrumentor, `xinstrument`, first constructs a parse tree of the source code. Parse-tree nodes that correspond to instrumentable program constructs are identified and appropriately, modified or transformed. The instrumented source-code is then obtained by “unparsing” the transformed parse tree. In order to gather sufficient data to reconstruct the complete dynamic behavior of the program, `xinstrument` has to identify every sequential block in the program. These usually consist of “straight-line code” between two instrumentable constructs. The example shown in Figure 4 uses a simple conditional to illustrate how the instrumentor and the monitor cooperate to capture control flow.

**Figure 4. Defining sequential blocks and arranging clocks around a conditional**

Xinstrument will insert two *extra*<sup>4</sup> clock-read statements inside the “then” portion of the conditional. Xinstrument also takes note of the target to which goto’s take place in its assignment of sequential blocks. New instrumentation has to be added to the application’s source code in order to capture or learn four elements of the application previously ignored:

1. Counts and duration: For each sequential block, information about how many times it was encountered and the total elapsed time for the code block is recorded.
2. Message patterns: At each send (and receive) construct, xinstrument inserts a learning module that attempts to capture the sequence of message tags (or ID’s) as well as the corresponding receivers (and senders).
3. Branch sequences: A learning module is inserted around each conditional to capture the branch sequence. Now suppose that the conditional (shown in Figure 4) was executed 10 times and only 2 of which succeeded. The monitor will observe 2 instances of clock sequence: *A-B-B’-C* and 8 instances of *A-C* (thus generating enough data to deduce which two out of those ten branches were successful).
4. Loop patterns: A learning module is inserted around each loop to capture the pattern of iteration sequence. The number of iterations a loop executes each time it is encountered can be different.

The data thus collected captures the control-flow of the entire program, thus enabling reconstruction of run-time behavior.

<sup>4</sup> Clocks A and C can be obtained for free because procedure calls are already instrumented and the times of foo’s termination and goo’s commencement can be deduced.

### 3.3 Monitoring

*AIMS*'s performance monitoring library, the *monitor*, defines a set of routines that *xinstru*-ment inserts into the application. They are responsible for initializing instrumentation and, gathering and storing performance data (see [YSM95]). Because only statistical data and fixed-length formulae are to be stored with this approach, the memory required for storing performance data for the entire execution at each node is fixed and predictable. All performance data is written to disk after program execution terminates.

The largest augmentation to the monitor involves the building of *learning modules* capable of deducing formulae to capture repeating sequences. A *learning module* must also perform efficiently to minimize run-time overhead and, at the same time, be able to recognize and encode a wide variety of sequences. As shown in Figure 5, a *learning module* basically operates as a finite state machine in which each "state" corresponds to a formula type that potentially describes the sequence.

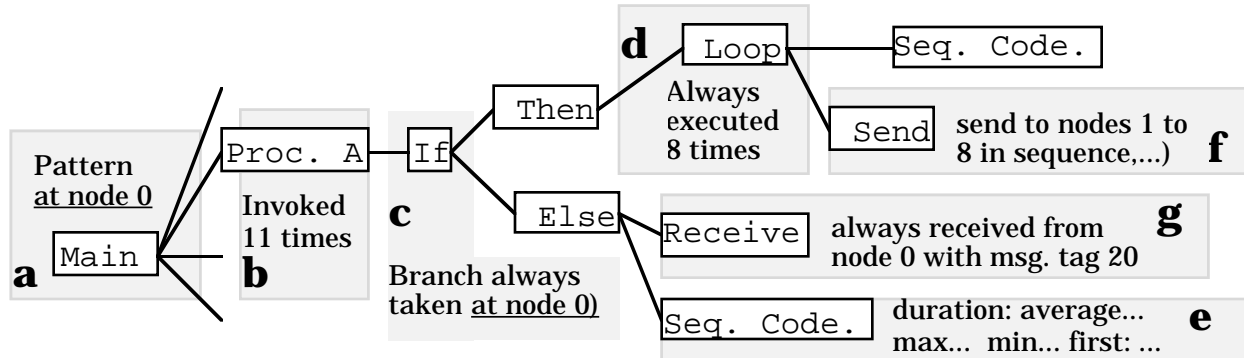

**Figure 5. A learning module is structured as a finite state machine**

At first, the module assumes the simplest and most frequent case<sup>5</sup>. As the next value in the sequence appears, the *learning module* attempts to confirm the correctness of the current proposed formula. When a discrepancy arises, the next possible formula is tested (in other words, a "state transition" occurs). When all (four) formulae fail to account for the newly observed value, the *learning module* concludes that the pattern cannot be learnt. The *learning module* is designed such that the process involved in comparing the next value against that predicted by the current formula is much cheaper than state transitions (*i.e.* testing a completely new formula) as they occur much less frequently. Therefore, the user may improve the predictive power of the module by appending more complex formulae (or in other words, adding more "states") to this engine. At the end of execution, all the formulae and statistics are written out to disk and ready for post-processing.

<sup>5</sup> Recall from section 2.3, four simple formulae have been identified (*c.f.* Table 4). Based on preliminary analysis of a few parallel applications (to be described in section The Experiments), the most common case is "ID" (which may represent a conditional in which the branch is always taken or a send construct sending to one recipient every time it is encountered).

### 3.4 Post-processing (Event Trace Reconstruction)

In order to construct a space-time view from the performance data (in the form of statistics and formulae) gathered using this approach, time-ordered events need to be generated. A simple algorithm has been implemented to accomplish this process:

**Figure 6. Annotated source tree ready for event-trace reconstruction**

1. BUILD PARSE TREE based on lexical information about the source code collected by `xinstrument`.
2. ANNOTATE PARSE TREE using performance data. As shown in Figure 6, the annotation process involves the association of performance statistics and formulae to instrumented constructs and sequential code blocks. These associations allow the reconstruction of elapsed times, branch sequences, iteration counts, and message receiver/sender/tag sequences in the next two steps.
3. RECONSTRUCT CONTROL FLOW via annotated parse tree traversal. Program execution is simulated as the parse tree is traversed node-by-node in lexical order. At specific points where control flow information was determined dynamically, *e.g.* the way a branch took or the number of times a loop executed, the stored formulae associated at that node is used (*c.f.* at points *c* and *d* of Figure 6).
4. GENERATE INTERVAL DURATION at each node. The amount of time spent at each node can be approximated by the statistical performance data associated at each parse-tree node.
5. CHECK CONSISTENCY OF EVENT TIMES ACROSS NODES when communication occurs. This process of ensuring messages are sent before they are received also facilitates periodical cross-checking and adjustment of elapsed times at each processing node, thus resulting in a more consistent picture of the entire execution (*cf.* with Figure 6, at point *f* for processing node 0 and point *g* for other nodes).
6. GENERATE TIMED EVENTS. The events are then collected as a time-ordered trace file for *VK* to build a space-time view.

## 4. The Experiments

### 4.1 Quality of Statistical Space-time Diagram

The methodology described here was applied to a few test programs and the NAS parallel benchmarks (NPB) [BB\*91]. To illustrate the quality of the space-time diagram generated from statistical data, three examples, `matmul` (Figure 7) and the NAS parallel benchmarks `SP` (Figure 8) and `BT` (Figure 9), were compared with actual event traces. It can be seen that the overall characteristics of event traces is correctly represented by the space-time view derived from statistics: 1) the control flow of program executions was correctly recorded, 2) critical points (such as message passing, global blocking) were illustrated, 3) the total execution time was very close. The exception of the durations of individual iterations of a loop in `matmul` (*c.f.* Figure 2) is due to that averaged durations were used in the construction of the space-time views from statistics.

**Figure 7. Space-time view for `matmul`: from a) event traces, and b) statistics gathered**

The total execution times of the six tested applications are summarized in Table 5. For a comparison, the corresponding values for uninstrumented and instrumented (*i.e.* event traces) are also included in the table. These values were taken from averages of three repeated runs for each application on 4 nodes of an IBM SP2. The overhead due to the instrumentation is reflected by 5 to 10% increase of execution time for the instrumented codes. The execution times for the two types of instrumentations (to produce event traces and statistical data) are very close. The slightly longer time (< 5%) to produce statistical traces is due to the extra cost of instrumenting control constructs, such as `IF` and `LOOP` statements, and the current implementation of the learning module.

**Figure 8. Space-time view for SP: a) from actual event traces, b) out of statistics gathered**

**Figure 9. Space-time view for BT: a) from actual event traces, b) out of statistics gathered**

Application	Problem Size	Uninstrumented	Instrumented		Stat.-Trace	
			exec. time	overhead	exec. time	overhead
matmult	200×1000	0.24 sec.	0.26 sec.	8.3%	0.26 sec.	8.3%
BT	40 iters 12×12×12	0.89 sec.	0.94 sec.	5.6%	0.97 sec.	8.9%
SP	40 iters 12×12×12	0.43 sec.	0.47 sec.	9.3%	0.50 sec.	16.3%
LU	40 iters 12×12×12	0.53 sec.	0.64 sec.	20.3%	0.70 sec.	32.1%
MG	40 iters 32×32×32	1.12 sec.	1.52 sec.	35.7%	1.64 sec.	46.4%
CG	15 iters 1400	1.09 sec.	1.12 sec.	2.8%	1.13 sec.	3.7%

**Table 5. Execution times (on IBM SP2) of uninstrumented vs. instrumented codes.**

## 4.2 Detailed Comparison of Trace Files

In order to describe the quality of the space-time views generated from statistical data quantitatively, a block-by-block comparison of trace records in the generated statistical trace (simplified as **Stat**) and the actual event trace (simplified as **Event**) has been performed. Two quantities are compared (as illustrated in Figure 10): the relative position of an event time,  $p = t'_i - t_i$ , and the time change of an execution block,  $d = b'_i - b_i$ , where  $b_i = t_{i+1} - t_i$  and  $b'_i = t'_{i+1} - t'_i$ . The first quantity,  $p$ , quantitatively compares how accurate two space-time views are in absolute terms, while the second quantity,  $d$ , indicates how close (or similar) two space-time views look in relative terms. Furthermore, discrepancies introduced in earlier parts of the execution impacts the quantity  $p$  but not  $d$  in later parts of the trace. These quantities are plotted as histograms for all the trace records for a given application and distributions, as illustrated in the right of Figure 10, are generated for a given bin-size. The spread of a distribution can be characterized by the standard deviation:

$$\sigma = \sqrt{\sum (p_i - \bar{p})^2 \rho_i}, \quad w = 2\sqrt{\ln 2} \sigma$$

where  $\bar{p}$  is the mean of the distribution,  $\rho_i$  is the probability, and  $w$  is the width at the half maximum ( $h$ ) for a Gaussian distribution. The spread is a direct indication of the closeness of two trace files. The comparison of block time ( $d$ ) is more realistic since it removes the uncertainty due to the program startup time and the progressive change due to different execution times.

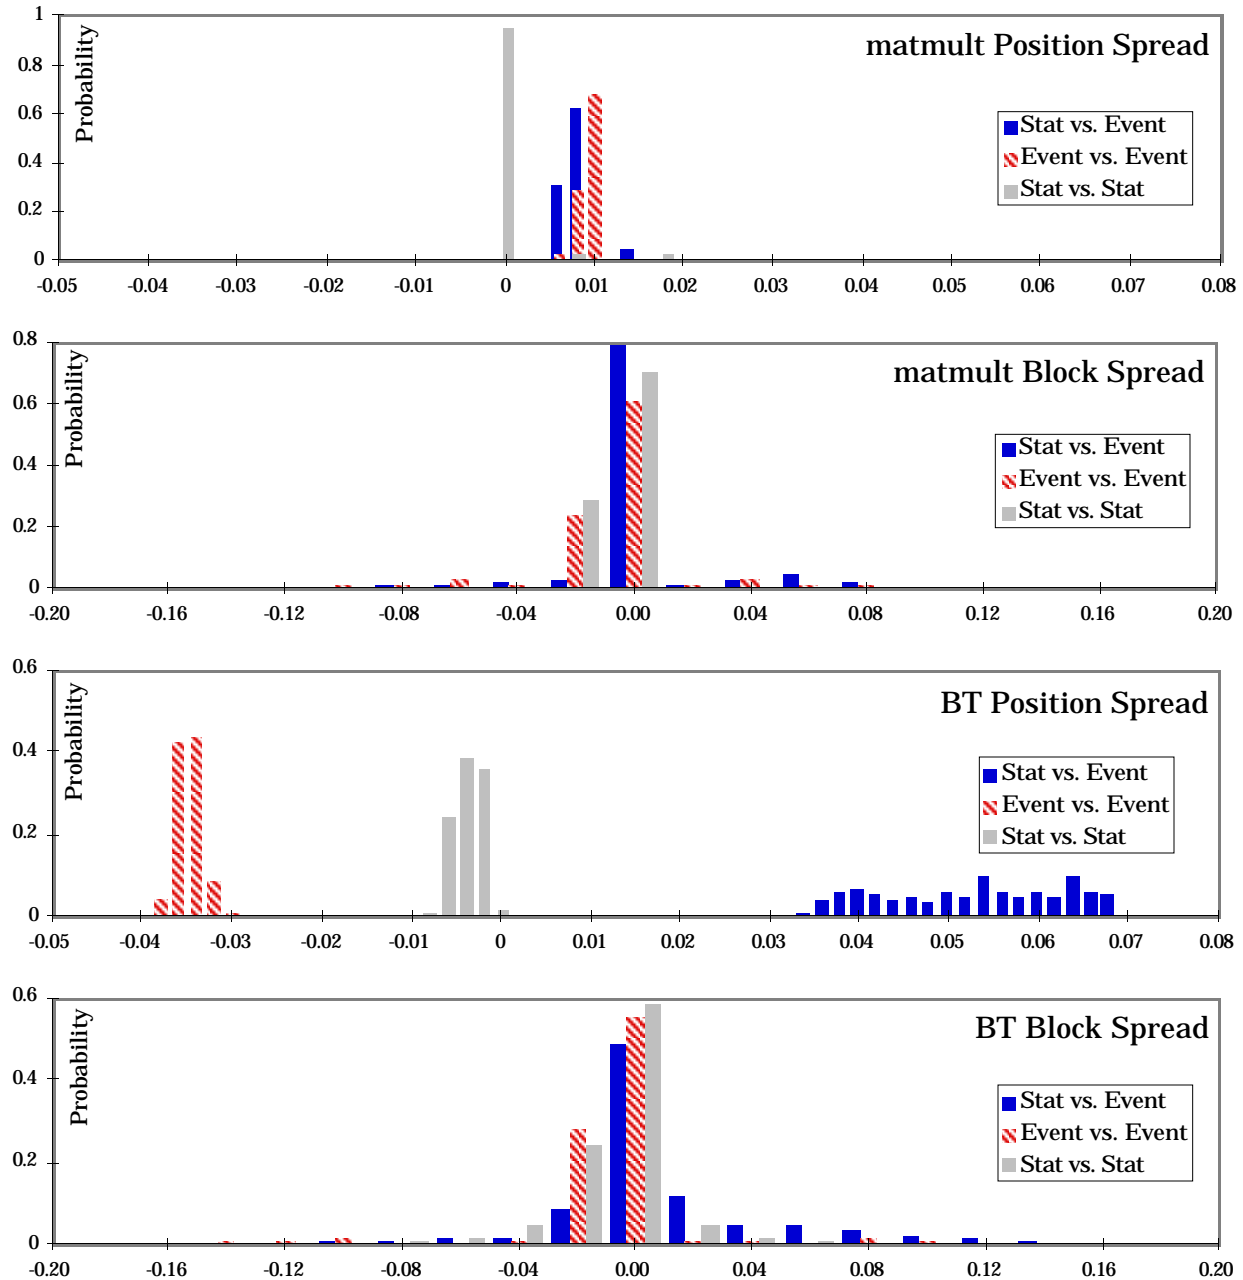

**Figure 10 a) Block-by-block comparison of trace records,  
b) Statistical (Gaussian) distribution with height  $h$  and width  $w$ .**

Three types of comparisons (*Event* vs. *Event*, *Stat* vs. *Stat*, and *Stat* vs. *Event*) have been done for six tested applications. The results for both position spread ( $p$ ) and block spread ( $d$ ) are summarized in Table 6. The spread of *Event*-vs.-*Event* indicates the natural spread of repeated program executions. This value is used as a reference for the other two types. A *quality factor* is defined as the ratio of a given spread and the reference spread and is also included in the table. A factor of one indicates that the fluctuation of time differences is within the natural spread, as illustrated by

the comparison of *Stat* vs. *Stat*. It is not surprising that the position spread of *Stat* trace vs. *Event* trace is much larger (quality factor is much smaller) than the corresponding block spread, as discussed in the previous paragraph. These differences can be seen from the distributions of  $p$  and  $d$  for MATMULT and BT shown in Figure 11.

**Figure 11. Position and block spreads of trace record times for matmult (a and b) and BT (c and d).**

The spread (or width) of *Stat* vs. *Stat* is slightly less than that of *Event* vs. *Event*: due to averaged information presented in statistical traces. The quality factor for *Stat* vs. *Event* is about 10%

worse (from the block spread) than that for *Event* vs. *Event*. This is a reflection of the use of averaged execution times for program constructs in the process of reconstructing the space-time view. This averaged representation would be distinguished in a real event trace, for example, execution time of a function call would be different with different input parameters, which could not be represented in the statistical trace.

	Position Spread ( $w$ )			Block Spread ( $w$ )		
Application	Event vs. Event	Stat vs. Stat	Stat vs. Event	Event vs. Event	Stat vs. Stat	Stat vs. Event
matmult	3.36	3.38 (0.99)	3.50 (0.96)	0.037	0.033 (1.11)	0.039 (0.95)
BT	3.48	3.36 (1.04)	15.1 (0.23)	0.039	0.038 (1.04)	0.047 (0.83)
SP	3.31	3.32 (1.00)	11.3 (0.29)	0.039	0.037 (1.06)	0.048 (0.81)
LU	3.29	3.29 (1.00)	5.00 (0.66)	0.035	0.034 (1.01)	0.037 (0.93)
MG	3.29	3.29 (1.00)	12.3 (0.27)	0.035	0.034 (1.03)	0.040 (0.87)
CG	3.56	3.86 (0.92)	5.50 (0.65)	0.042	0.033 (1.27)	0.044 (0.95)

### 4.3 Trace File Size

Experiments have also been performed on trace file sizes. Figure 12 compares the variation of trace file size when SP and BT are executed with a problem size of  $12 \times 12 \times 12$ . It is not surprising that the size of event trace files increases linearly as the problem size goes larger, while the size of statistical files remains constant. Based on this data, we can easily project that for full-scale executions (with problem size  $162 \times 162 \times 162$  for 200-400 iterations) it will be very difficult to use event tracing to obtain performance data. More experiments on various parallel programs (such as other NAS Parallel Benchmarks) are performed and similar results are obtained since the proposed methodology is designed to produce a small fixed length trace file.

As can be seen from the next section, the use of fixed length *formulae* in the statistical tracing enables us to capture more than 90% of the execution sequences, and with the increase of formula size this percentage also increases, yielding always predictable trace file size. For those truly *random* execution sequences, multiple or variable-length formulae may be used although the size of the resulted trace file may increase. However, since random execution sequences usually are very small percentage (less than a few percent) of the whole program execution, the change of the trace file size is expected to be nominal (less than a few percent of the increase in a real event trace file).

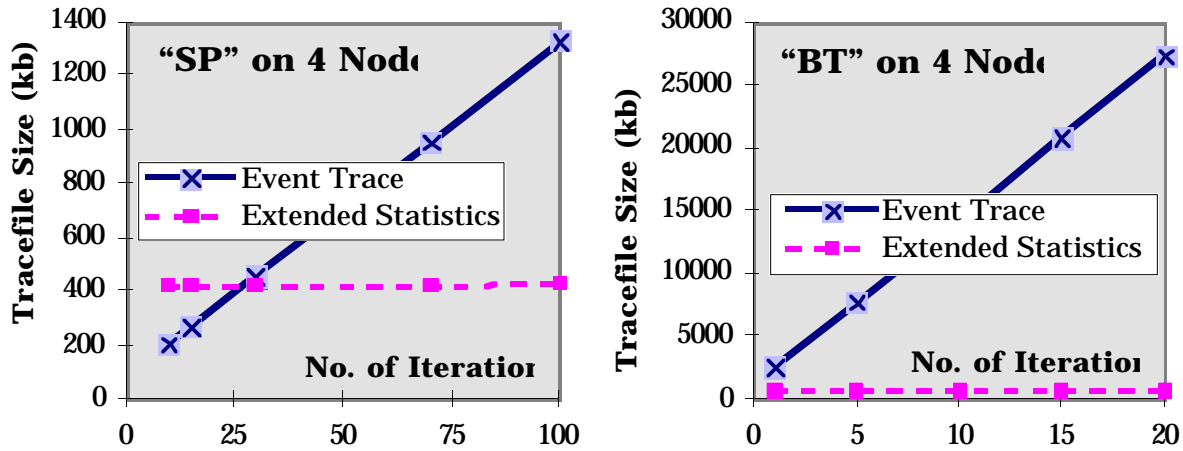

Figure 12. Trace file size comparison

In summary, the space-time view derived from the statistical data (stat-trace) gives a reasonable representation of the overall trace picture with critical points accurately demonstrated (important for performance analysis). The use of stat-tracing eliminates the need of trace flushing in the middle of program execution and, thus, produces trace file with less distortion and predictable size. When problem size gets very large, event trace becomes very large and statistical trace wins.

#### 4.4 Ability to Capture Application Characteristics

Perhaps many readers are wondering how effective these four formulae were in capturing sequences associated with parallel applications. Figure 13 puts the applications tested along two axes. The y-axis, labeled “No. of Individual Send/Recv Constructs”, measures the (static) complexity of the source code. The x-axis, labeled “No. of messages Sent”, measures the

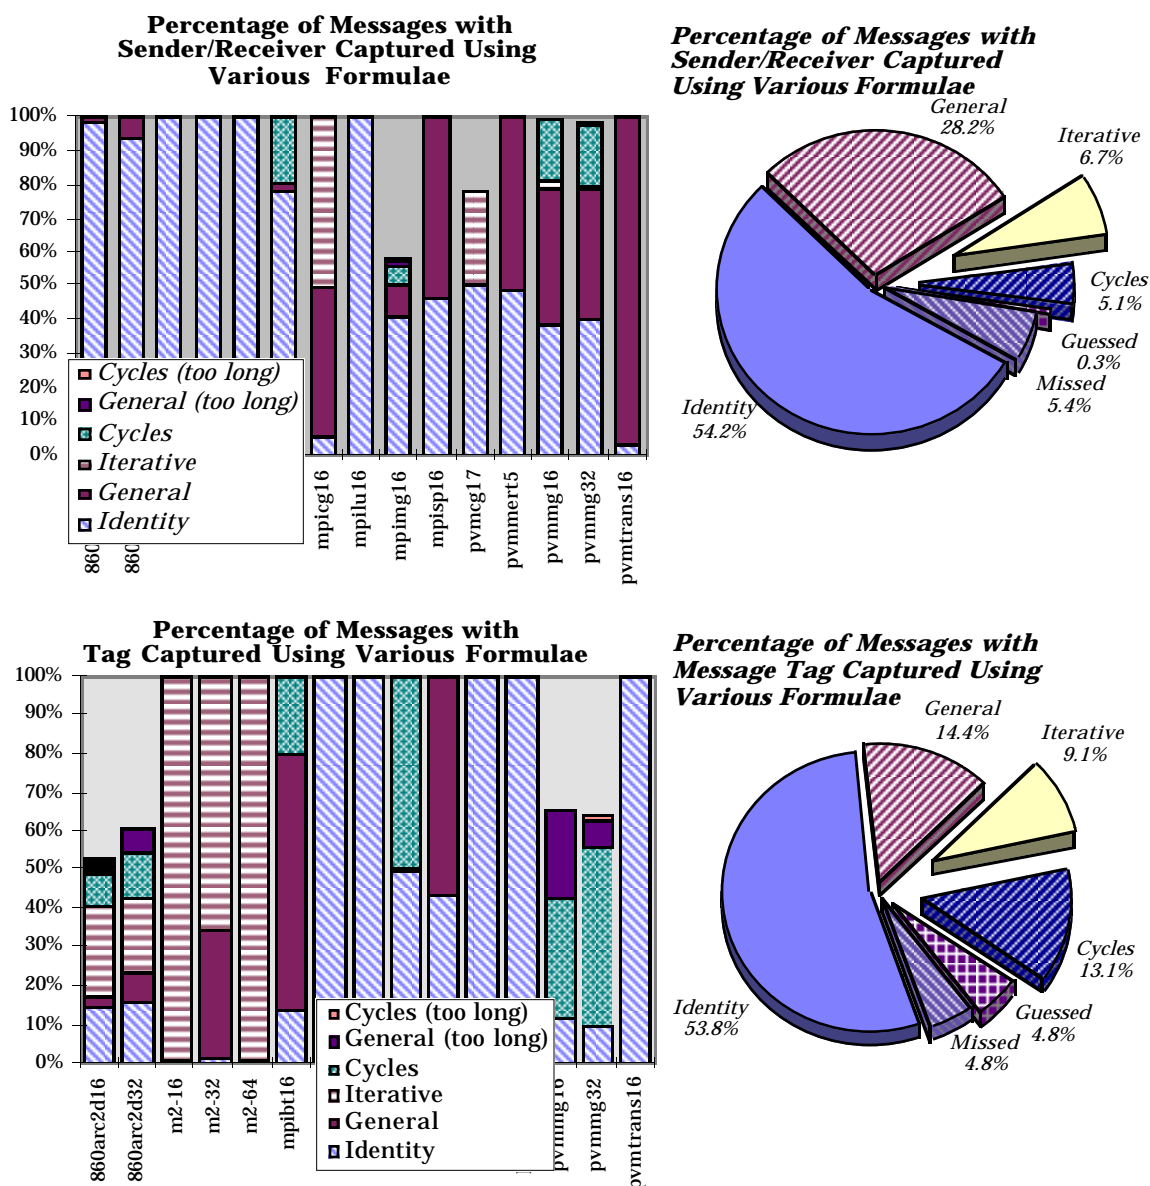

Figure 13. Characteristics of applications tested

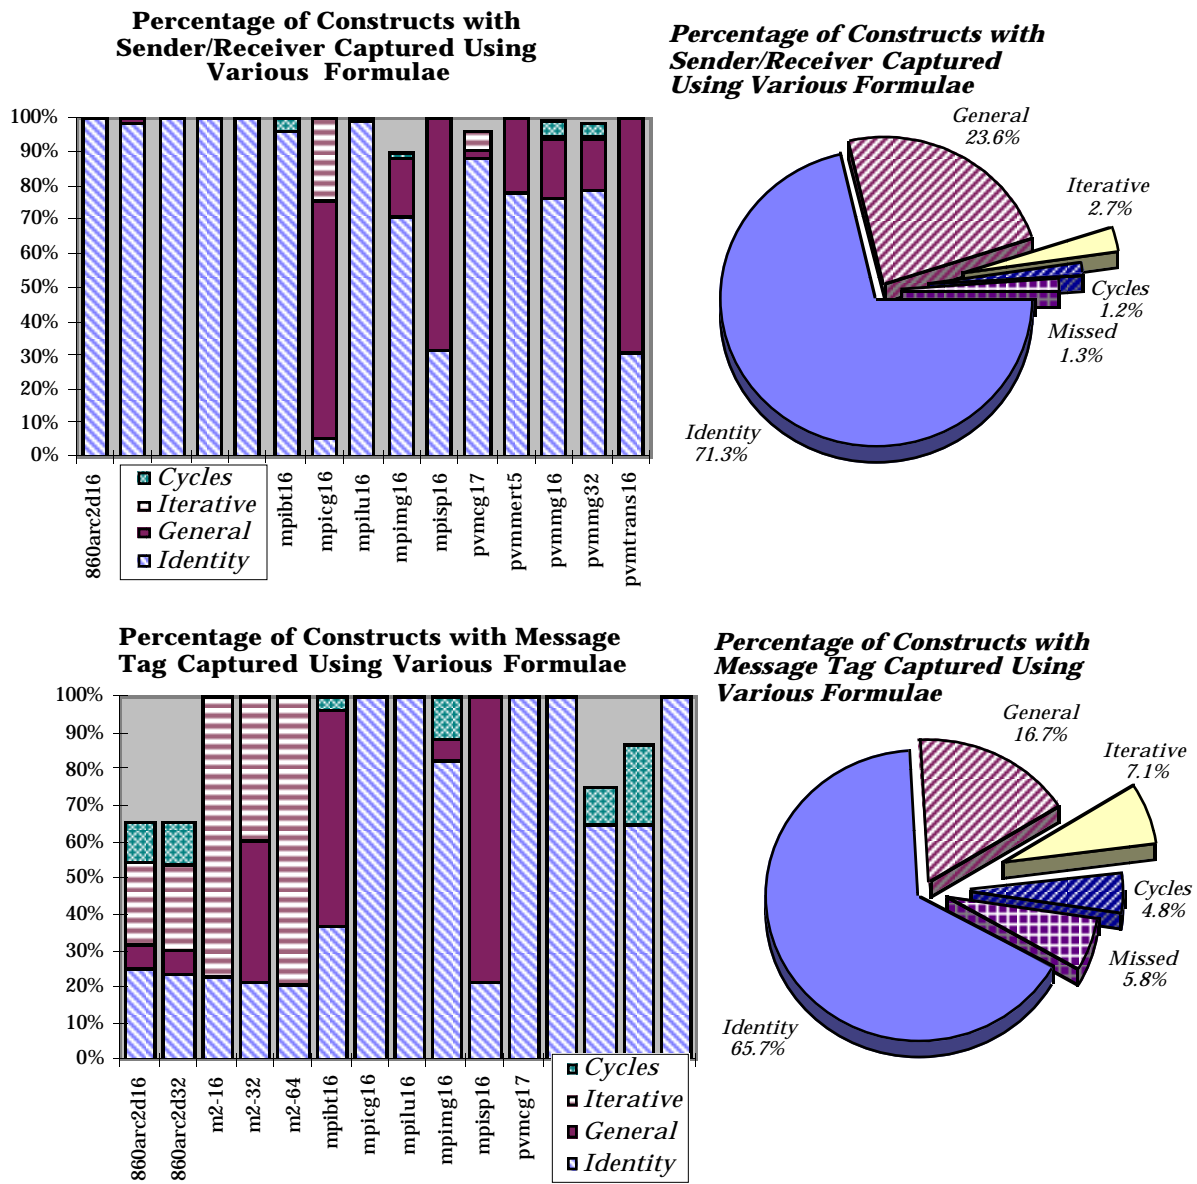

(dynamic) execution complexity. It suffices to say that most programs consist of hundreds of individual send/receive constructs sending tens of thousands of messages during execution. These represent fifteen PVM and MPI programs executed on 8 to 64 nodes on the Intel Paragon, IBM SP2, as well as a network of workstations (on various data sizes). Again due to length considerations, only results related to message sending and receiving are reported. The nature of branch sequences and loop iteration counts are much simpler and will be reported in a future paper.

**Figure 14. Ability of formulae to capture message tags used in 15 applications**

The ability of various formulae to capture message tags and sender/receiver used are shown in Figure 14 and Figure 15 respectively. There are four charts in each figure; the top two represent static counts — showing percentages of constructs in the source code learnt whereas the bottom

two represent dynamic counts — showing percentages of messages actually sent during execution. The pie charts on the right represent summaries of the detailed data displayed on the left.

**Figure 15. Ability of formulae to capture senders/receivers used in 15 applications**

A number of observations can be made. First, the formulae capture all message tags in 11 test cases and all sender/receivers in 13 of the 15 test cases<sup>6</sup>. Second, the “ID” formula accounts for most cases: in other words, most programmers use a constant in their code for message tag and

<sup>6</sup> The reader should note that the percentage of sequences learnt depends on the length of formulae. The data presented here represent formulae of a maximum sequence length of 18. Longer sequences can be learnt by allocating more memory for monitoring at run-time.

sender/receiver. Finally the reconstruction algorithm can actually obtain some of the numbers in the sequences up to the point where the formula failed.

Some preliminary experiments were carried out to study the effect of formula length. Figure 16 shows the performance of the formulae averaged over all the applications. It can be seen that as expected, allocating more memory indeed, captures longer sequences and thus allows more sequences to be learnt. The designed simple formulae can learn more than 90% of the patterns with a given formula length. In principle the failed percentage of patterns (*e.g.* from random sequences) can be eliminated by starting a new learning cycle, *i.e.* use of multiple formulae for a given pattern, or by dynamically increasing the formula length. The increase of trace file size is expected to be nominal and should be a few percentage of the increase of a real event trace file.

**Figure 16. Effect of formula length on percentages of message tags and senders/receivers learnt**

## 5. Conclusions and Future Work

In summary, an innovative approach has been proposed for performance instrumentation, monitoring, trace data representation, and execution reconstruction. This approach is based on the assumptions that program behavior is, in general, not random and that critical control flow information (such as branch sequences, loop bounds, and message tags/senders/ receivers named in communication calls) can be represented using repeating sequences. Furthermore, the length of these sequences is short (on the order of the number of nodes participating in the computation) and can be captured and regenerated using simple formulae. This approach requires a completely new set of instrumentation to be inserted into the application before compilation and a new set of tools for reconstructing execution history.

This methodology has been tested with fifteen applications, most of which consist of the NAS Parallel Benchmarks. There are four major results:

1. The data files thus obtained are, indeed, small, bounded and predictable before program execution.

2. The quality of the space-time views generated from these statistical data is excellent.
3. Experimental results show that the formulae proposed were able to capture 95% of the sequences involving message sending and receiving (the most complicated among the six categories mentioned in section 4.4). This corresponds to 100% of all the sequences associated with 11 of the 15 applications.
4. The performance of the formulae can be incrementally improved by allocating more memory at run-time to learn longer sequences.

By the use of variable-length formulae or multiple formulae, execution sequences can be learnt 100%. However, the impact on the trace file size needs further investigation. More experiments are needed to study the intrusion of the learning module and extra instrumentation on control flows, which may pinpoint to future improvements of our implementation. In particular, work still needs to be performed in two major areas to fully evaluate the applicability of this approach for actual systems:

Dealing with unknowns — Sequences that are either very long or truly non-repeating (*e.g.* as a result of non-determinism) cannot be learned. Even though experimental results suggest that these comprise less than 5% of the sequences associated with the programs we tested, they pose potential problems for event trace reconstruction. Message lines cannot be drawn on the space-time diagram when sequences associated message transmission cannot be reconstructed. Failure to reconstruct sequences associated with control-flow is much more problematic; the “remedy” depends on the type, past behavior and the context in the particular control-flow construct occur. In some cases, these potentially problematic constructs can be identified at instrumentation time and the user can be alerted to provide alternatives. Otherwise, the monitor can decide to fall-back on event-tracing for this small percentage of construct, still resulting in a much smaller trace file than a “pure event trace”.

Characterizing and reducing run-time overhead — Although the most intrusive element for event tracing (namely the need to flush trace records to disk) has been eliminated, more constructs are instrumented and the cost of executing complex learning modules could become expensive. Nevertheless, with the current formulations and test cases, this mode of monitoring exerts less overhead than event tracing.
